Suppose we measured for 40 subjects (p = 1, 2, ..., 40) their average heart rate  $(h_p)$  and the amount of coffee they drank  $(c_p)$  during a day. We can do a linear regression between these two variables:

$$h_p = \beta_0 + \beta_1 c_p + \varepsilon_p$$

This is a very cool model with two parameters:  $\beta_0$  indicating an intercept and  $\beta_1$  indicating a slope.

There are several reasons for doing a linear regression:

- ullet We want to get a significant p-value
- We want to see if coffee can predict someones heart rate
- We want to make a nice picture

We can easily fit this model using the lm() function in R:

By running coef(fit) we can look at the estimates for  $\beta_0$  and  $\beta_1$ . We can also look at anova(fit) to look at if the regression is significant.

Linear regression is cool, but do remember this quote by George Canning:

I can prove anything by statistics except the truth.
